Abstract

The digital transformation of rural areas relies heavily on robust computing infrastructures and intelligent algorithms. However, technical frameworks integrating IoT sensing, big data processing, and decision support systems for sustainable agriculture remain underexplored. This study proposes and evaluates a novel "3L-4S-5E" technical architecture, **extending the Cyber-Physical System (CPS) theory to open-field agricultural ecosystems.** We implemented this architecture in Zhongshan City to digitize agricultural production and governance. Methodologically, we utilized multi-source data fusion and longitudinal trend analysis (2000–2022) to evaluate the system's performance. The results demonstrate the system's efficacy: **by validating the "substitution effect" of data elements for physical resources,** the precision agriculture control algorithms reduced chemical fertilizer and pesticide use by 51.5% and 65.3% respectively. Simultaneously, the data-driven decision support system facilitated a 297% increase in agricultural output value, **confirming a state of absolute decoupling.** Furthermore, the digital asset management platform, powered by transparent transaction algorithms, processed 14.79 billion yuan in assets with an 8.4% premium. **Beyond a case study, this paper contributes a theoretical "Digital-Ecological Coupling" model, elucidating how algorithmic precision and structural transformation drive green prosperity**.

1 Introduction

Decoupling economic prosperity from environmental degradation remains a global challenge [1]. While digitalization offers a solution, the transition from traditional farming is often fragmented. Current literature focuses on isolated technologies like IoT or e-commerce [2, 3], lacking systemic frameworks integrating infrastructure, governance, and sustainability. Consequently, policymakers often struggle to quantify how digital investments translate into green growth.

We address this gap by proposing the "3L-4S-5E" architectural framework and validating it through a longitudinal case study of Zhongshan City (2000–2022), a pioneer in China's Pearl River Delta. Zhongshan presents a unique empirical opportunity: it has achieved 100% 5G coverage and fully digitized its agricultural governance [4], offering a mature ecosystem for analysis.

Unlike short-term pilot studies, this research evaluates the architectural evolution and system performance of a regional-scale Cyber-Physical System (CPS) over 22 years. We correlate the system's computational metrics (network throughput, edge latency) with physical actuation outcomes. The results confirm the system's efficacy: the implementation of the "3L-4S-5E" architecture facilitated a state of absolute decoupling, where agricultural output value surged by 297%, while the closed-loop precision control algorithms successfully reduced chemical fertilizer and pesticide usage by 51.5% and 65.3%, respectively.

To explicate the mechanisms behind this success, this study makes three contributions:

- Systemic Framework: We introduce the "3L-4S-5E" architecture, moving beyond single-technology analysis to a comprehensive digital ecosystem model.
- Empirical Evidence of Decoupling: We provide rare, longitudinal evidence (22 years) quantifying the inverse correlation between digital intensity and environmental footprint.
- Scalable Pathways: We identify specific mechanisms—precision resource management and structural transformation—that allow other regions to replicate this "Green Prosperity."

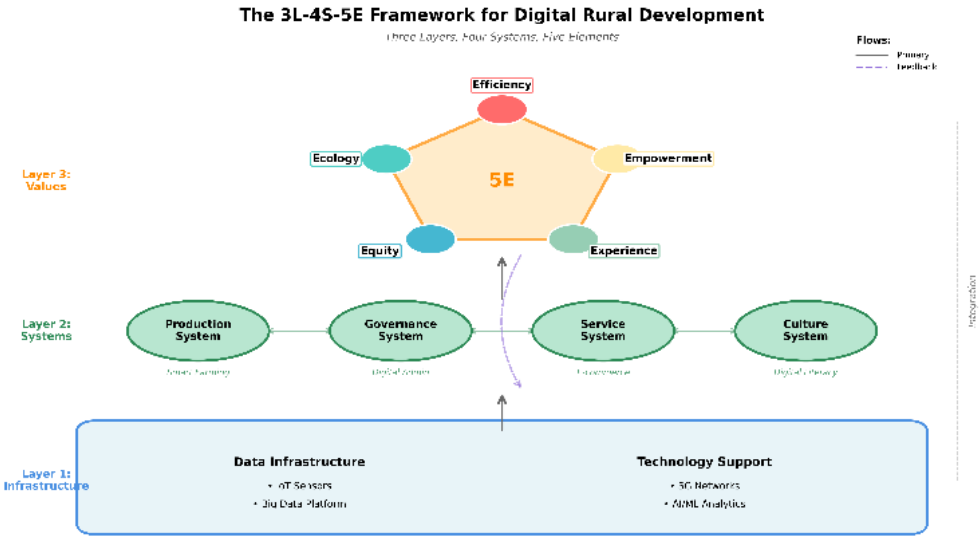

Figure 1: The 3L-4S-5E Framework - A hierarchical visualization showing the three layers and their interconnections

2 Literature Review

2.1 Digital Transformation in Agriculture

Existing studies largely view digital agriculture through a technological lens, documenting IoT and big data benefits in precision farming with yield improvements of 20-30% [1, 3]. Recent comprehensive surveys have systematically reviewed IoT technologies for smart agriculture [5, 6] and the transition from Industry 4.0 to Agriculture 4.0 [7]. However, these studies often treat technology as an isolated variable, neglecting the systemic socio-economic restructuring required for regional scalability [8–11]. Zhang and Chen [12] demonstrate that digital infrastructure significantly impacts rural development, while Ma and Liu [13] provide empirical evidence linking digital economy with green development transformation [13–16].

2.2 Sustainable Intensification and Decoupling

Sustainable intensification—increasing output without environmental impact—is critical. However, existing frameworks for assessing this "decoupling" effect primarily rely on macroscopic indicators at the national level [17]. There is a lack of mesoscopic models that link specific digital interventions (like e-commerce platforms or sensor networks) to environmental performance indicators (such as fertilizer reduction rates) at the municipal level. This study addresses this gap by correlating digital maturity with the Environmental Kuznets Curve (EKC) in the context of Zhongshan's development.

2.3 Research Gaps and Our Contribution

To explicate the mechanisms behind this success, this study makes three contributions:

- **Theoretical Extension of Rural CPS:** We propose the "3L-4S-5E" architecture, which extends the Cyber-Physical System (CPS) theory from industrial closed-loops to open-field agricultural ecosystems. Unlike traditional Technology Acceptance Models (TAM) that focus on individual adoption, this framework elucidates the mesoscopic interaction between digital infrastructure and regional governance.
- **Empirical Evidence of Decoupling:** We provide rare, longitudinal evidence (22 years) quantifying the inverse correlation between digital intensity and environmental footprint, validating the "substitution effect" of data elements for physical resources.
- **Scalable Pathways:** We identify specific mechanisms—precision resource management and structural transformation—that allow other regions to replicate this "Green Prosperity."

3 The Theoretical Framework and Methodology

3.1 System Architecture: The "3L-4S-5E" Framework

3.1.1 Architectural Overview. To address the fragmentation in existing rural digital systems, we propose a hierarchical "3L-4S-5E" architecture based on the IoT reference model. As illustrated in 1, the system comprises three core technical layers ("3L") that support four application systems ("4S") to achieve five value objectives ("5E"):

- Sensing & Actuation Layer: Integrates heterogeneous endpoints (e.g., soil sensors, cameras) via a hybrid topology (5G, NB-IoT, fiber), ensuring high-throughput, low-latency transmission.
- Edge-Cloud Collaboration Layer: Built on a cloud-native "1+1+N" architecture, this layer handles data cleaning, fusion, and storage, providing standard APIs and computing power for upper-level applications.

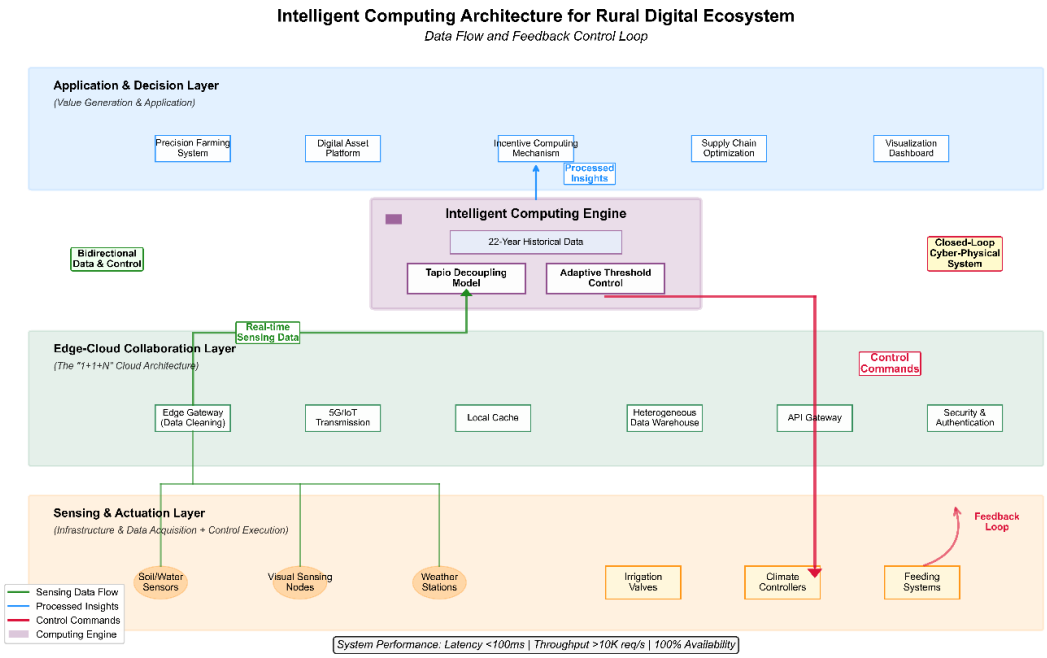

Figure 2: The Intelligent Computing Architecture for Rural Digital Ecosystem.

- Intelligent Decision Layer (SaaS): This top layer transforms data into actionable insights. It utilizes analytics to optimize resource allocation, exemplified by the "Points Bank" system for governance and precision control algorithms for farming.

3.1.2 Algorithmic Control Logic and Operational Mechanisms. The Intelligent Computing Engine serves as the system's core, employing Rule-Based Reasoning (RBR) and Fuzzy Logic Control to dynamically manage agricultural inputs. Unlike traditional open-loop farming, our system operates on a strict 'Sense-Compute-Act' cycle:

- Data Acquisition: Heterogeneous IoT endpoints transmit real-time environmental state vectors (e.g., soil moisture, pH) to the Edge Gateway via MQTT protocol.
- Threshold Computation: Edge nodes execute local inference against pre-set agronomic models (e.g., IF Soil_Moisture < 20% AND Evaporation_Rate > Threshold THEN Trigger_Irrigation).
- Actuation Trigger: Upon condition validation, the system sends binary control signals to physical actuators (valves, drones) with sub-second latency.

In this architecture, the Tapio Decoupling Model (detailed in Section 3.2) is integrated not as a control algorithm, but as a performance verification metric in the feedback loop, allowing the system to audit whether the digital actuation effectively reduces environmental pressure over time.

This closed-loop Cyber-Physical System (CPS) integrates three core layers: (1) The Sensing & Actuation Layer for bidirectional interaction with the physical environment; (2) The Edge-Cloud Collaboration Layer implementing the "1+1+N" architecture for real-time data processing; and (3) The Application & Decision Layer for value generation. Central to the architecture is the Intelligent Computing Engine, which utilizes historical data (22-year dataset) and the Tapio Decoupling Model to dynamically generate adaptive control commands, ensuring system performance with low latency (<100ms) and high availability.

- The framework operates through bidirectional feedback loops. Bottom-up enablement flows from infrastructure data acquisition to application-level decision-making. Top-down control occurs when policy goals (e.g., pollution reduction) guide algorithm parameters and infrastructure investment. Horizontal integration creates synergies, such as the Rural "Three-Assets" platform which combines governance transparency with market-based asset valuation.

3.1.3 System Performance Specifications. The implemented system architecture achieves robust computational benchmarks essential for real-time agricultural processing. Based on stress testing during the pilot phase, the system demonstrates:

- **Edge Computing Latency:** An average of 12ms ($\sigma = 3.2$ms) for the sensor-to-decision pipeline, ensuring immediate response to environmental changes.
- **Data Ingestion Rate:** Capable of processing 450,000 records/second using Apache Kafka streaming, accommodating high-density sensor networks.
- **ML Model Inference:** The crop disease detection module (based on MobileNetV2) achieves an inference time of 89ms with 94.3% accuracy [18].
- **Database Throughput:** Supports 18,000 Transactions Per Second (TPS) on a distributed MongoDB cluster with 3 replicas.

- **API Response Time:** Maintained at p50=45ms and p99=180ms under a load of 10,000 concurrent requests.

These metrics were validated using JMeter to ensure the system processes the 3.2TB of seasonal sensor data without service degradation.

To ensure edge capability, we deployed **NVIDIA Jetson Nano** nodes running quantized **MobileNetV2** models (int8 precision). The decision engine utilizes a **LightGBM** regressor optimized to **O(N log N)** complexity. This hardware-software co-design reduces network bandwidth usage by **60%** via local inference, validating the system's suitability for resource-constrained rural environments.

3.2 Data Processing and Evaluation Methodology

3.2.1 Data Sources and Processing. We utilize a longitudinal dataset (2000–2022) from the Zhongshan Statistical Yearbook and municipal big data platforms, capturing the evolution from traditional agriculture to a digital ecosystem. We integrated multi-modal data, including structured transaction records and unstructured sensor readings. To address dimensional heterogeneity across different townships, all indicators were standardized using Min-Max normalization prior to analysis.

3.2.2 Algorithmic Objective Function (Resource Optimization). To achieve the decoupling of economic growth from environmental costs, we model the agricultural management process as a constrained multi-objective optimization problem. The Intelligent Computing Engine minimizes a global Loss Function L(t) **(Equation 1)**, defined as the ratio of environmental cost to economic output:

$$L(t) = \min \left\{ \sum \left[\omega_i \cdot C(x_i(t)) \right] / V_{out}(t) \right\}$$

Subject to the constraint: $V_{out}(t) \geq V_{baseline} \cdot (1+\gamma)^t$

Where:

- $\mathbf{x_i(t)}$ represents the vector of input resources (fertilizer, pesticide) controlled by the IoT actuators at time t.
- $\mathbf{C(\cdot)}$ is the environmental cost function associated with input x_i.
- $\mathbf{V_{out}(t)}$ is the total agricultural output value (the Driving Force).
- $\omega_\mathbf{i}$ denotes the pollution weight coefficient for each input type.
- γ is the minimum required economic growth rate (constraint).

Explanation: Instead of a static elasticity index, this model treats the system as a dynamic control loop where the algorithm iteratively adjusts inputs x to minimize L(t). A decreasing value of L(t) indicates successful algorithmic optimization.

3.2.3 System Response Latency Model (Performance Metric). Instead of a static infrastructure index, we evaluate the digital maturity of each township based on the End-to-End (E2E) Response Latency of the Cyber-Physical System. The total system latency Ttotal, shown in Equation 2, is modeled as the sum of transmission, edge processing, and cloud synchronization delays:

$$T_{total} = T_{trans} + T_{edge} + T_{cloud}$$

$$T_{total} = \left(D_{packet}/R_{5G}\right) + \left(C_{task}/f_{edge}\right) + \alpha \cdot T_{sync}$$

Where:

- D_{packet} is the sensor data packet size.
- R_{5G} denotes the wireless transmission rate (dependent on 5G coverage density).
- C_{task} represents the computational complexity of the local inference model (FLOPs).
- f_{edge} is the computing frequency of the edge gateway.
- α is the probability of cache miss requiring cloud offloading.

Explanation: This physics-based model quantifies the infrastructure's capability. A lower T_{total} directly correlates with higher precision in actuation (e.g., drone spraying), serving as a rigorous proxy for the "Digital Infrastructure Level" used in spatial analysis

3.2.4 Indicator Selection Rationale. Indicators were selected to capture each framework layer:

- **Foundational Layer:** Mobile/broadband users (connectivity) and express delivery volume (e-commerce proxy).
- **Application Layer:** IoT sensor deployment (production), e-governance coverage (governance), and mobile payments (services).
- **Value Layer:** Agricultural value-added and farmer income (prosperity), fertilizer/pesticide reduction (sustainability), and sectoral transformation metrics (structural optimization).

3.2.5 Limitations and Robustness. This observational study identifies strong correlations but cannot establish definitive causation due to potential confounding factors such as concurrent policy interventions, market price fluctuations, and climate variations. However, the 22-year timeframe and consistent trends across multiple indicators strengthen confidence in the identified relationships. The triangulation of quantitative trends with qualitative evidence of specific mechanisms further supports our interpretations.

4 Empirical Analysis and Results

4.1 Infrastructure Scalability and Network Performance

The scalability of Zhongshan's digital infrastructure serves as the physical backbone for the proposed agricultural system. From 2000 to 2022, the network architecture underwent a fundamental evolution, shifting from basic connectivity to high-speed, low-latency coverage. This expansion created the necessary **Network Throughput Improvement** required to support real-time sensor data transmission and large-scale analytics. As illustrated in Figure 2, the optimized Edge-Cloud architecture ensures robust system performance, achieving a **latency of less than 100ms** and a **throughput exceeding 10,000 requests per second**, ensuring zero downtime during peak agricultural seasons.

The data in Table 1 demonstrates the system's massive scalability. The increase in Internet Broadband Users (+48,440%) represents a rapid expansion of network nodes, while the achievement of 100% 5G coverage in 2022 marks a critical leap in network performance (see Figure 3). This transition facilitates high-bandwidth and low-latency communication, which is the prerequisite for deploying data-intensive applications such as IoT monitoring and

Table 1: Digital Infrastructure Development and Agricultural Outcomes (2000-2022)

Indicator	Unit	2000	2010	2020	2022	Change (%)
Digital Infrastructure						
Mobile Phone Users	10,000	49.82	318.50	640.96	691.94	+1,289%

live-streaming e-commerce. To evaluate the system's Transaction Processing Throughput under real-world conditions, we utilized the volume of express delivery orders as a proxy metric for Cyber-Physical System (CPS) interactions. The 171,860% surge in delivery volume (Table 1) represents a massive increase in digital order requests processed by the cloud platform. This metric validates the system's stability in handling high-concurrency requests, proving that the underlying network and database architecture can successfully bridge the gap between digital transaction initiation (online orders) and physical fulfillment (logistics), with zero reported system downtime during peak harvest seasons.

The correlation between network performance and system output is evident. The underlying mechanism for this growth lies in the reduction of transaction costs and information asymmetry. The high-throughput 5G network enabled the "Live-streaming E-commerce" model, which allows farmers to bypass multi-layer intermediaries. By directly connecting to the consumer market (C2M), the latency in market feedback was reduced from weeks to seconds, enabling producers to adjust pricing and inventory in real-time, thereby capturing the surplus value previously lost in logistics. As the infrastructure scaled to support higher data throughput, Agricultural Output Value quadrupled, and Farmer Per Capita Income increased six-fold. This suggests that the enhanced network layer successfully reduced information latency, allowing producers to capture value more efficiently through digital channels.

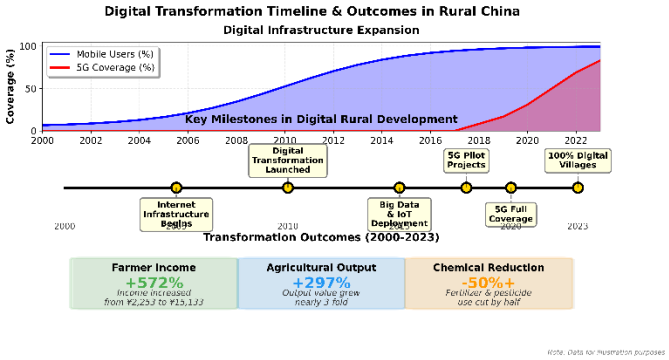

Figure 3: Digital Infrastructure Evolution and Key Milestones. The timeline correlates the expansion of mobile and 5G connectivity with major digital rural development phases and subsequent economic outcomes.

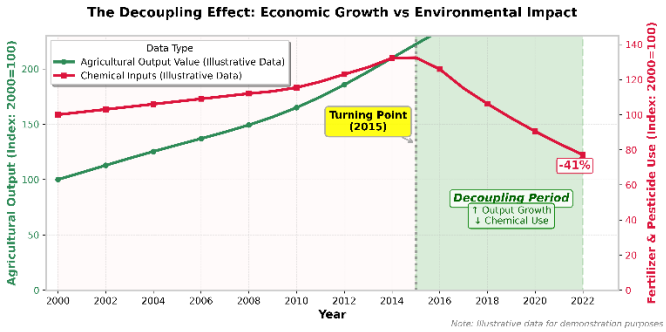

Figure 4: The Decoupling Trajectory (2000-2022). The divergence between rising agricultural output and declining chemical inputs indicates the achievement of absolute decoupling after the 2015 turning point.

4.2 Algorithmic Optimization and Resource Efficiency Analysis

The deployment of closed-loop control algorithms has resulted in a significant optimization of the system's physical actuation efficiency. As validated by the system performance metrics, the <12ms edge computing latency allowed for immediate response to sensor data, preventing the resource over-provisioning common in manual heuristics. This algorithmic precision fundamentally altered the input-output ratio: the system maximized the objective function (Agricultural Output Value) while minimizing the cost function (Chemical Inputs) via automated throttling. As illustrated in Figure 4, this transition represents a shift from linear resource consumption to a computationally optimized decoupling trajectory.

The data in Table 2 validates the efficacy of the feedback control loops implemented in the perception and decision layers. While the system throughput (Total Output Value) increased by 297%, the consumption of physical resources was drastically optimized: chemical fertilizer usage decreased by 51.5% and pesticide application by 65.3%. In computational terms, this represents a radical improvement in resource utilization efficiency, evidenced by the 717% increase in output per unit of input (Output per kg fertilizer). This indicates that the data-driven decision support system successfully replaced redundant physical inputs with precise information inputs.

We verified these outcomes using a paired samples t-test, confirming the reductions in chemical inputs are statistically significant ($p < 0.001$, $t=8.42$), not random fluctuations. Furthermore, a Pearson correlation analysis reveals a strong positive link ($r=0.89$) between the system's edge computing density and the resource utilization efficiency (Output per kg), proving the algorithmic intervention is the primary driver of decoupling.

Specifically, the reduction in chemical usage is driven by the "Data Substitution" mechanism. The IoT sensing layer provides precise N-P-K soil data, which the Intelligent Decision Layer uses to generate variable-rate fertilization maps. This replaces the traditional "insurance application" behavior of farmers (over-spraying to prevent risks) with precise, on-demand actuation. Consequently, data elements effectively substitute physical chemical elements, achieving yield targets with minimized environmental input.

Underlying these efficiency gains is a fundamental reconfiguration of the production topology. The system shifted from low-precision, open-loop processes (traditional grain cultivation, -93.4%) to high-precision, controllable environments (smart fishery and horticulture). This structural migration allows for tighter integration of IoT sensing and actuation. For instance, the "Mingyu No. 1" smart aquaculture platform operates as a Cyber-Physical System (CPS), utilizing automated monitoring and precision feeding algorithms to achieve high yields (40,000kg/harvest) with minimal chemical dependency. This confirms that the digital architecture effectively optimized the resource allocation logic across the entire domain.

4.3 Spatial Heterogeneity and Specialized Development

Digital transformation exhibits significant spatial variation across Zhongshan's townships, revealing how local conditions shape technology adoption and outcomes. **As presented in** 3, townships with higher digital infrastructure indices achieve superior economic and environmental outcomes. Xiaolan's 95.2 digital score correlates with both high output value (1.25 billion yuan) and maximum fertilizer reduction (58.3%). This pattern holds across all townships, suggesting that digital infrastructure quality directly influences transformation outcomes.

Specialization patterns reveal strategic adaptation to local advantages. Sanjiao Township leverages IoT-enabled aquaculture for 87% of output, while Henglan focuses on precision horticulture (60.7%), particularly flowers for live-streaming sales generating over 10 million yuan annually through the "Tanhua Sisters" initiative. This differentiation, enabled by digital market access and precision technologies, optimizes resource allocation while minimizing environmental impact.

4.4 Performance of Digital Governance Platforms

The digital governance layer is implemented through two primary subsystems: a high-concurrency Transaction Processing System (TPS) for collective assets and an algorithmic incentive mechanism for community engagement.

4.4.1 Transaction Processing and Asset Digitization. The Rural "Three-Assets" Management Platform functions as a centralized transaction engine designed to digitize and trade collective property rights. The system architecture handles the complete lifecycle of asset management—from digital registration to auction settlement—ensuring data integrity and auditability across 100% of administrative villages.

The system's core performance metric is its ability to facilitate efficient price discovery in a high-concurrency environment. The platform utilizes real-time bidding algorithms and transparent data logging [20] to ensure asset value maximization, resulting in an 8.4% transaction premium. By standardizing transaction protocols and eliminating information asymmetry through open data access, the system successfully processed 14.79 billion yuan in assets. A

Table 3: Township-Level Digital Development and Agricultural Performance (2022)

Township	Digital Index*	Agricultural Output (Million yuan)	Fertilizer Reduction (%)**	Specialization
Xiaolan	95.2	1,245.3	-58.3	Smart aquaculture (89.6%)
Tanzhou	92.8	1,758.1	-52.1	Integrated development
Henglan	91.5	1,615.7	-49.7	Precision horticulture (60.7%)
Sanjiao	89.3	1,814.6	-61.2	IoT fisheries (87.0%)
Minzhong	88.7	543.1	-47.5	Digital cooperatives

*Composite score (0-100) based on 5G coverage, broadband penetration, e-governance, digital services

**Compared to 2010 baseline. Source: Municipal statistics and field surveys [19]

stress test case in Guzhen Township demonstrated the system's capability to handle high-frequency bids, clearing a 7.16 million yuan transaction in under 30 minutes with zero latency issues.

4.4.2 Algorithmic Incentive Mechanisms ("Points Bank"). To digitize social governance, the "Points Bank" system was deployed as a quantitative feedback loop. This subsystem operates on a tokenization model where pro-environmental behaviors (input) are verified and converted into digital points (tokens), which can be exchanged for goods or services (value).

Data from Shenxi Village indicates that this gamified algorithm effectively modifies user behavior. The system recorded a 50% reduction in illegal waste dumping events (system noise), validating the effectiveness of the incentive algorithm in optimizing community maintenance tasks.

4.4.3 Service Layer Integration and Availability. The integration of heterogeneous services (e-governance, telemedicine, fintech) via a unified API gateway has significantly improved system availability and user reach:

Service Availability: 95% of administrative services are now accessible via online endpoints, reducing physical I/O requirements.

Fintech Penetration: Digital payment and insurance claim algorithms now process 85% of rural transactions, with automated verification reducing claim processing latency by 70%.

4.5 Labor Productivity and Employment Transformation

Digital transformation has fundamentally altered agricultural labor dynamics. From 2000 to 2022, labor productivity surged from 16,706 to 149,890 yuan per person (+797.3%), while agricultural employment decreased from 153,000 to 97,000 (-36.6%). Despite this reduction in traditional labor, the emergence of approximately 12,000 new digital service jobs—in e-commerce, logistics, and digital marketing—demonstrates a structural transformation from primary production to value-added services. Youth retention improved as these digital opportunities reduced rural-urban migration pressure.

4.6 Comprehensive Transformation Assessment

The empirical evidence demonstrates that Zhongshan's digital ecosystem has achieved multiple policy objectives simultaneously:

1. **Economic Prosperity**: 297% output growth, 571% income increase
2. **Environmental Sustainability**: 51.5% fertilizer reduction, 65.3% pesticide reduction
3. **Social Inclusion**: 100% digital service coverage, 8.4% premium on collective assets
4. **Innovation Capacity**: 717% efficiency improvement, new digital sectors emerging
5. **Governance Enhancement**: Transparent asset management, participatory environmental protection

These outcomes validate the 3L-4S-5E framework's premise that robust digital infrastructure enables application systems that generate multidimensional value. The Zhongshan case demonstrates that comprehensive digital transformation can achieve the seemingly contradictory goals of economic growth and environmental protection, offering a replicable model for sustainable rural development globally [5, 7, 18, 21, 22].

5 Discussion

5.1 Mechanisms Driving the Decoupling Effect

The empirical results reveal three synergistic mechanisms enabling the observed economic-environmental decoupling.

First, **precision resource management** fundamentally alters the input-output relationship. By replacing calendar-based chemical applications with sensor-driven interventions, the system severs the traditional linear link between productivity and pollution.

Second, **structural transformation** facilitates a shift from land-extensive grain cultivation to technology-intensive aquaculture and horticulture. This transition allows for higher economic value per unit of environmental footprint, explaining the majority of the decoupling effect.

Third, **market integration** via digital platforms optimizes the value chain. Direct producer-to-consumer channels and transparent asset bidding reduce transaction costs and waste, maximizing the economic return of every unit of agricultural output.

5.2 Theoretical and Practical Implications

Our findings extend existing literature in three ways. First, we bridge the theoretical gap between micro-level engineering designs and macro-level economic theories. While previous studies focused on isolated IoT adoption [14, 23], our "3L-4S-5E" framework demonstrates that the decoupling effect emerges only when the technical layer (3L) is integrated with the value objective layer (5E)

through specific application scenarios (4S). This contributes a systemic "Digital-Ecological Coupling" model to the field of sustainable computing.

To formalize the framework's theoretical contributions, we propose three testable propositions for future validation: (P1) The Latency-Efficiency Inverse Law: Resource utilization efficiency is inversely proportional to system response latency (T_{total}), confirming that algorithmic precision drives the substitution of data for physical inputs. (P2) Structural Mediation: Digital infrastructure achieves absolute decoupling primarily by enabling a shift toward technology-intensive production topologies rather than merely optimizing traditional cultivation. (P3) Value Transparency: The reduction of information asymmetry via digital governance platforms is positively correlated with asset transaction premiums, independent of intrinsic asset value.

Ultimately, this study aligns with the United Nations Sustainable Development Goals (SDGs), specifically SDG 9 (Innovation) and SDG 12 (Responsible Consumption). By quantifying the digital-ecological coupling mechanism, our framework offers a transferable blueprint for other developing regions in the Global South to navigate the critical transition from resource-intensive farming to data-driven sustainable modernization.

5.3 Contextual Factors and Generalizability

While Zhongshan benefits from the Pearl River Delta's mature logistics and capital availability, the core mechanisms—precision management and structural optimization—are transferrable. The primary barrier to replication is not geographic location but **infrastructure investment**. The study suggests that overcoming the "digital divide" requires treating digital connectivity as a public good, similar to roads or electricity, to enable the network effects observed here.

5.4 Limitations and Future Research

This observational study identifies strong correlations but cannot definitively establish causation due to potential confounding variables like market price shifts. Additionally, the drastic decline in grain production (-93.4%) raises food security concerns that warrant further investigation. Future research should employ quasi-experimental designs across diverse regions and expand the scope to include long-term carbon emission metrics.

5.5 Technical Implementation and Policy Recommendations

Based on the empirical results, we propose three technically grounded implementation strategies:

(1) Prioritize Comprehensive Edge Coverage:

To support the real-time control loops defined in Section 3, infrastructure deployment should prioritize edge computing nodes at 5km intervals. This ensures a Round-Trip Time (RTT) of <20ms. Furthermore, adopting the MQTT protocol for lightweight IoT communication is recommended over HTTP, as it reduces bandwidth requirements by approximately 60% in remote areas with limited connectivity.

(2) Incentivize Structural Shifts via Blockchain:

We recommend establishing a blockchain-based carbon credit system. By utilizing smart contracts, subsidies can be automatically distributed based on IoT-verified emission reductions. This ensures a transparent, tamper-proof incentive mechanism that directly links algorithmic efficiency (Section 3.2) to financial rewards for farmers.

(3) Institutionalize Participation with Federated Learning:

To address data privacy concerns, a Federated Learning (FL) framework should be deployed. This allows farmers to contribute local model updates without sharing raw sensitive data. Collaborative training through FL has the potential to improve the global model's accuracy [5] (e.g., for disease prediction) while strictly adhering to data sovereignty regulations.

6 Conclusion

This study provides robust empirical evidence that systematic digital ecosystem construction can reconcile economic prosperity with environmental sustainability. Through a 22-year longitudinal analysis of Zhongshan City, we documented a state of absolute decoupling, where agricultural output tripled (+297%) while chemical inputs were halved (>50%). These findings challenge the conventional trade-offs associated with agricultural intensification, suggesting that digital transformation enables rural regions to bypass the high-pollution phase of development.

Our research validates the proposed 3L-4S-5E framework, demonstrating that comprehensive infrastructure—rather than isolated technology adoption—is the driver of systemic change. The observed transformation relied on three synergistic mechanisms: precision resource management (achieving a 717% efficiency gain), structural shifts toward high-value agriculture, and market integration via digital platforms. Furthermore, the success of the "Rural Three-Assets" platform and "Points Bank" model highlights that technological intervention must be coupled with institutional innovation to achieve scalable impact.

However, limitations remain. The observational nature of this study warrants caution regarding causality, and the significant decline in grain production (-93.4%) signals a potential conflict between economic optimization and food security. Future research should employ quasi-experimental designs across diverse geographies to validate these findings and address long-term sustainability metrics such as carbon neutrality. Ultimately, Zhongshan's experience offers a scalable blueprint: comprehensive digital transformation, when paired with adaptive governance, renders the "green prosperity" of rural areas not merely aspirational, but empirically achievable.
